ABSTRACT

Background and objectives: Pregnancy-induced hypertension (PIH) is a serious pregnancy complication that contributes significantly to both maternal and neonatal morbidity and mortality. The study aimed to evaluate various hematological parameters associated with PIH and to identify early hematological parameters predictive of eclampsia and hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome.

Methods: A total of 114 subjects were studied. Venous blood samples were collected to study hematological profile, including coagulation and biochemical analysis.

Results: Of 114 subjects, 35 were categorized as gestational hypertension, 33 as mild preeclampsia, 40 as severe preeclampsia, and six as eclampsia. Eight cases progressed to HELLP syndrome. The mean hemoglobin level was 10.6±2.1 g/dl, which decreased significantly in PIH patients as the disease progressed (p=0.045). The mean platelet count was 191 ± 84 x 10⁹ cells/L. The mean platelet count in PIH patients decreased significantly with disease progression (p=0.008). The mean prothrombin time and activated partial thromboplastin time were 13.12 ± 1.33 and 33.62 ± 6.34 seconds, respectively. These parameters also increased significantly with disease progression (p<0.05). Liver enzymes, creatinine, and uric acid levels increased significantly as the disease progressed (p<0.05).

Conclusion: Most of the hematological parameters changed as PIH progressed in severity. The mean levels of hemoglobin, platelet, and lymphocytes are lower in cases with PIH, while the mean prothrombin time and activated partial thromboplastin time are higher in these patients. These variables are sensitive and specific prognostic markers for patients with PIH.

Keywords: Pregnancy induced hypertension; thrombocytopenia; coagulation profile; HELLP syndrome

INTRODUCTION

Pregnancy-induced hypertension (PIH) is one of the most common pregnancy complications, affecting approximately 5-7% of all pregnancies. It is also a significant cause of maternal and fetal morbidity and mortality (1). The incidence of PIH in India ranges from 5% to 15% (2). The most common immediate maternal complications of PIH are eclampsia, oligohydramnios, accidental hemorrhages, disseminated intravascular coagulation, and hemolysis, elevated liver enzymes and low platelets (HELLP) syndrome. Remote complications include residual hypertension, recurrent preeclampsia, and chronic renal failure (3). The most common fetal complications of PIH are intra uterine growth retardation, intra uterine death, prematurity, and asphyxia. Many hematological changes are seen in association with PIH, thrombocytopenia being the most common (4,6). Changes are also seen in peripheral smear, coagulation profile, and liver enzymes. This study was done to aid clinicians in early detection, monitoring, and management of cases with PIH.

Preeclampsia develops a variety of hematologic aberrations, which affect the outcome of the patients. In such cases, supportive therapy can be initiated to prevent maternal and neonatal morbidity and mortality. From the standpoint of prevention, preeclampsia has remained a challenge for obstetricians. Various strategies have been proposed to reduce the perinatal effects of preeclampsia. This can be achieved by early diagnosis of preeclampsia simply via assessment of blood coagulation profile (7,9). Complete blood count, urine examination, and liver function tests performed to identify platelet abnormalities, red cell abnormality, and to detect patients who progress to HELLP syndrome.

This study was done to compare hematological indices in patients with gestational hypertension, mild preeclampsia, severe preeclampsia and eclampsia to identify early detection of the disease, and

its management to reduce morbidity and mortality of mother and fetus.

MATERIALS AND METHODS

This study was done in the Department of Pathology, Narayana Medical College and Hospital, Nellore, India. This was a prospective study conducted from October 2013 to September 2015 on 114 antenatal PIH cases. Inclusion criteria were >20 weeks of gestation, blood pressure (BP) of >140/90 mmHg, and $\geq 1+$ proteinuria. Previously known cases of hypertension, bleeding disorders, and preeclampsia superimposed on a known case of essential hypertension were excluded. All patients with coexisting medical, surgical or gestational conditions were excluded. The number of patients recruited in this study was calculated using the formula $N = Z^2P(1-P)/d^2$ where N is the sample size, Z is the statistic corresponding to level of confidence, P is expected prevalence, and d is precision (10). Considering 95% confidence interval, expected prevalence of 10.3% (11), and absolute precision of 5%, the required sample size was calculated as 114. All samples were collected with the support of the Department of OBG, Narayana Medical College, India.

Data collection

Preliminary data of patients with PIH were collected at admission, coded, and recorded into a master chart. The patients were followed up until perinatal period for final diagnosis and evaluation of disease progression. Venous blood samples were collected in EDTA tubes for hematological profile, in sodium citrate tube for coagulation studies, and in plain tubes for biochemical analysis. The hematological parameters were assessed using an autoanalyzer (LH 780, Beckman Coulter, USA). Erythrocyte sedimentation rate (ESR) was determined using disposable Westergren's tubes. Automated blood coagulation analyzer (IL ACL 7000 Coagulation Analyzer, Diamond Diagnostics Inc. USA) and the biochemical

analysis using automated analyzer (Human Humastar 600 Chemistry Analyzer, Diamond Diagnostics Inc. USA). The findings were recorded as per the proforma. The master chart was prepared having preliminary data (hospital ID, age, gravid status, and BP) as well as hematological and biochemical values. The cases were categorized as gestational hypertension (BP: 140/90 mmHg, no proteinuria), mild preeclampsia (BP: 140/90 – 160/110 mmHg, proteinuria+), severe preeclampsia (BP: >160/110 mmHg), and eclampsia (BP: >140/90 mmHg, seizures+). Various parameters and peripheral smear examinations were studied among these groups.

Statistical analysis

Data were analyzed using the Chi-square test. Statistical analysis was carried out in SPSS (version 22), and *p*-values less than 0.05 were considered as statistically significant.

RESULTS

Of 114 subjects, 35 were categorized as gestational hypertension, 33 as mild preeclampsia, 40 as severe preeclampsia, and six as eclampsia.

Eight patients (7.01%) consisting of seven cases of severe preeclampsia and one case of eclampsia progressed to HELLP syndrome. As shown in [figure 1](#), the peripheral smear examination showed schistocytes and anisopoikilocytosis in these cases.

Figure 1. Hemolytic picture with many schistocytes (A) and marked anisopoikilocytosis with schistocytes (B)

As shown in [table 1](#), the mean levels of hemoglobin (Hb), platelets, prothrombin time (PT), international normalized ratio (INR), partial thromboplastin time (aPTT), aspartate transaminase (SGOT), alanine transaminase (SGPT), alkaline phosphatase (ALP), creatinine, and uric acid differed

significantly between patients in different groups. As shown in [table 2](#), the level of Hb, PC, SGOT, SGPT, and urea differed significantly between cases with HELLP syndrome and those without HELLP syndrome ($p \leq 0.05$).

DISCUSSION

Preeclampsia is one of the leading causes of maternal and fetal morbidity and mortality. After active research for many years, the etiology of PIH remains unclear. Evidence suggests that there were several underlying causes for endothelial dysfunction such as hypertension, proteinuria, and edoema, as well as preeclampsia (12). In the present study, important hematological, coagulation, and biochemical values were compared among various groups of PIH. The frequency of patients with gestational hypertension, mild preeclampsia, severe preeclampsia, and eclampsia was 30.7%, 28.9%, 35.1%, and 5.3%, respectively. The majority of patients were in the 20-30 years age group. The present study showed that primigravid patients were equally affected with hypertensive disorders in pregnancy as multigravid patients.

In normal pregnancy, there is an increase in erythropoietic activity, but due to increase in plasma volume, there is a fall in hemoglobin concentration. Normal physiological changes also affect the hematological parameters during pregnancy; hence, maternal anemia is common (12). The percentage of patients with anemia increased with disease severity. We detected a significant decrease in hemoglobin levels with the increase in disease severity. In the present study, 33.3% of the subjects had anemia. The mean hemoglobin concentration was 10.6 g/dl with a standard deviation of 2.12, which is almost comparable to the values reported by Navamar et al. (13) and Alisi et al. (14).

In a study by Monteiro et al., hemoglobin and platelets levels were significantly decreased in cases with preeclampsia (12). In our study, there was a significant reduction in the platelet count as PIH progressed. Platelet count variations in pregnant women with PIH may be due to increased consumption with decreased life span and increased aggregation caused by increased levels of thromboxane A₂ in placental circulation (15). Compared to previous studies (13, 14), we obtained

higher mean platelet counts, which might be related to the inclusion of patients with gestational hypertension in whom hematological changes are more subtle.

In the present study, 42.1% of patients had thrombocytopenia. Similar studies by Burrows RF and Kelton JG (16) reported prevalence rates of 50% and 34%, respectively.

The mean platelet count in the present study ($191 + 84 \times 10^9$ cells/L) was similar to that in previous studies (13, 17, 18). In our study, ESR increased in few patients, but no ESR rise was seen with increase in disease severity. The mean ESR value in the present study was 71.85 (mm/hr), which is higher than the value reported by Monteiro et al. (57.87 (mm/hr)) (12). In normal pregnancy, ESR may rise due to increased fibrinogen and globulin levels and reduced blood viscosity. In our study, eight cases (7.01%) had features of HELLP syndrome. A similar incidence rate (6%) was found in a study done by Sultana et al. (2). However, some studies reported much higher incidence rates (18, 19).

In this study, 27.19% of patients showed increased PT levels, and PT values observed to be increased significantly according to the increased disease severity. Similar to our findings, Shetty et al. reported a significant increase in PT levels in PIH cases (20).

In this study, the mean PT values in cases with mild preeclampsia, severe preeclampsia, and eclampsia were $12.80 + 1.11$, $13.02 + 1.53$, and $13.61 + 1.33$ seconds, respectively. This indicates that PT value increases significantly as PIH progresses. The mean PT values obtained in different forms of the disease were comparable to the values reported by Nirmala et al. (21) and Chauhan et al. (22).

There was a significant increase in aPTT with increase in the severity of the disease. In addition, 20.17% of the patients had increased aPTT level. The mean aPTT in this study was 33.62 seconds, which is similar to the value reported by Dave et al. (23) and Orlikowski et al (24). The mean aPPT was varied in the studies conducted by

Chaware K et al (18), Nirmala et al (21) and Chauhan et al (22).

When compared with normal pregnancy, there is a significant increase in hepatic enzyme activity in preeclampsia. Liver damage adversely affects protein metabolism, which in turn could affect erythropoiesis. Reduction in red blood cell and platelet count may be a consequence of liver damage (14).

In the present study, the mean SGOT and SGPT levels were 39.58 ± 32.57 IU/L and 26.75 ± 25.85 IU/L, respectively, which are similar to the levels reported by Munazza et al. (25) and Bhowmik et al. (26). Our study identified significant increase in SGOT/AST and SGPT/ALT ratio as the disease progresses.

The levels of urea, creatinine, and uric acid were increased in patients with PIH when compared to normal individuals, indicating impaired renal function in PIH. These findings are in agreement with findings of some previous studies (12, 14, 27). Uric acid is one of the most sensitive indicators of disease severity in PIH and can help in monitoring disease progression. In preeclampsia, uric acid level has been known to be increased and correlates with maternal and fetal morbidity (20). Wake et al. claimed that plasma uric acid level could help to predict development of eclampsia in subjects with preeclampsia (28). Hawkins et al. reported hyperuricemia as an important finding in PIH because it predicts risk of adverse fetal outcomes, even in women with gestational hypertension without any other features of preeclampsia (29). Mustaphi et al. found a strong positive correlation between levels of serum uric acid and severity of PIH (30).

The present study showed that there is significant increase in the Uric acid levels as the disease progresses, which was comparable to other studies (12, 31).

Some variables such as aPTT, SGOT, and urea levels were higher in cases with HELLP syndrome. In the present study, serum SGOT levels were higher in HELLP cases compared with non-HELLP PIH

cases, which is consistent with findings of Shetty et al. (20).

CONCLUSION

Hematological changes such as anemia, thrombocytopenia, and deranged coagulation profile as well as altered liver and renal parameters are seen in PIH. The degree of thrombocytopenia, anemia, and deranged parameters increases as the disease progresses from gestational hypertension to eclampsia. Changes in the liver and renal parameters were prominent in cases of HELLP syndrome, which can be used for earlier identification of these patients. The results show that repeated blood test could help in careful monitoring, early detection, and appropriate management of PIH in order to reduce risk of morbidity and mortality.
