### Abstract

**Background and objectives:** Intraoperative awareness is accidental or unintentional awareness during general anesthesia that occurs when complete anesthesia has not been achieved. The aim of this study was to investigate the occurrence of awareness with recall during general anesthesia in opium-addicted and non-addict patients undergoing abdominal and pelvic surgeries.

**Methods:** The study population consisted of patients undergoing abdominal and pelvic surgeries under general anesthesia in two hospitals in Gorgan, Northeast of Iran. Data were collected 20-36 hours after the surgery using a three-part questionnaire on demographic information, surgery and anesthesia details and anesthesia awareness and recall of events. Data were analyzed in SPSS (version 18) using the Chi-square test.

**Results:** Of 206 patients, 53.9% were male and 56.3% were undergoing abdominal surgery. None of the patients in the two groups felt hearing, pain, cold or heat during anesthesia, and neither of them dreamed or recalled any event during the anesthesia and surgery period. There was no statistically significant difference between the two groups in terms of anesthesia awareness with recall. According to the patients, the night before the operation, opium addicts were more anxious the night before the surgery and felt more pain right after the surgery.

**Conclusion:** There is no statistically significant difference in terms of occurrence of anesthesia awareness between opium-addicted and non-addicted patients undergoing pelvic and abdominal surgeries. However, opium addicts experience significantly higher level of anxiety the night before surgery compared to non-addicts. In addition, opium addicts experience more pain immediately after recovery.

**Keywords:** Anesthesia Awareness, Recall, General anesthesia, Opium addiction

## INTRODUCTION

The term "anesthesia awareness" is a universally accepted phenomenon defined as recalling events during general anesthesia after surgery (1, 2). General anesthesia is a drug-induced reversible condition characterized by unconsciousness, amnesia, analgesia and akinesia (3) created by a balance between the amount of anesthetics administered and the patient's arousal (1). Recall is the patient's ability to retrieve memories that are assessed by the patient's reports of past events, especially those that occurred during general anesthesia (4, 5). The prevalence of anesthesia awareness varies from 0.11% to 43% in adults and 5% in children (5-7).

Causes of awareness and recall during general anesthesia include the followings: 1. Light anesthesia for some surgeries such as cesarean section and emergency surgeries; 2. Increased need for anesthetics for patients who are often resistant to anesthetics, such as young patients and consumers of tobacco, alcohol, narcotics or amphetamines. 3. Malfunction of the anesthesia machine; 4. Not delivering enough anesthetics to the patient due to an empty evaporator or N<sub>2</sub>O cylinder.

If the patient is awake during the operation and able to hear conversations, he will feel weak, paralyzed, helpless, anxious and afraid of death. It may also lead to a series of complications including sleep disturbances, nightmares and anxiety during the day, which may be transient or long term. In severe conditions, it may lead to post-traumatic stress disorder (8, 9). The patient also fears that this may be repeated in the future if anesthesia is needed (9). The occurrence of anesthesia awareness depends on the anesthesia methods and the study population. For example, opium addicts require a higher dose of anesthetics because of tolerance to anesthetics (10-12). The issue of anesthesia awareness is currently being reevaluated due to the suggestions of recent studies that consciousness is a common

occurrence and associated with unintended consequences (13). Identifying risk factors and possible reasons for the occurrence of anesthesia awareness may help prevent this issue and its complications. Determining the proper medication regimen will provide a safe and mentally healthy anesthesia for the patient, which will ultimately improve health and reduce the cost of treatment in patients undergoing surgery. Since drug addiction can increase the likelihood of awareness during anesthesia, the present study was conducted to investigate the occurrence of awareness and recall during general anesthesia in opium-addicted and non-addicted patients undergoing abdominal and pelvic surgeries.

## MATERIALS AND METHODS

In this study, the study population consisted of patients undergoing elective abdominal and pelvic operations under general anesthesia in the 5 Azar and Sayyad Shirazi Education hospitals in Gorgan, Iran. Written consent was obtained from all participants and the study received approval from the Ethics Committee of Goletan University of Medical Sciences, Gorgan, Iran. Inclusion criteria were classes 1, 2 and 3 anesthesia, age of over 16 years, verbal and auditory health and lack of mental illness. Exclusion criteria included emergency surgeries, postoperative stay of less than 24 hours and addiction to alcohol, methamphetamines, etc.

Based on the study of Malek et al. and considering the prevalence rate of 13% and 1.6% anesthesia awareness in opium-addicted and non-addict individuals, 80% power and 5% error, sample size of 78 was considered for each study group. Taking into account the exclusion of study subjects, with a 30% increase in sample size, 103 people were considered for each group. Subjects were enrolled via convenience sampling.

The patients were examined by an anesthesiologist before surgery. After 10 hours fasting, the patients entered the

operating room in supine position and the drugs were administered prior to the operation. Preoperative prodrugs including midazolam (2.5 mg), fentanyl (25-100 µg) and metoclopramide (10 mg) or ondansetron (4 mg) were used. Anesthesia was induced with 3-5 mg/kg nesdonal and 0.5-4 mg/kg atracurium muscle relaxant, and maintained with 1.5 MAC isoflurane and nitrous oxide (50%). To restore relaxant effects, 0.05-0.07 mg/kg neostigmine and 0.1-0.2 mg/kg atropine were administered. Preoperative fluid therapy was performed equally for all patients by calculating the amount of fluid required for the patient and considering the duration of fasting and the patient's bleeding rate. During general anesthesia, the patients underwent standard monitoring including continuous monitoring of heart rate and electrical activity, blood pressure and red blood cell oxygen saturation. The results were recorded every 15 minutes.

Data were collected using a three-part questionnaire on demographic information, surgical and anesthesia information (ASA score, duration of anesthesia, administered drugs as well as duration, site and type of surgery) and anesthesia awareness with recall. The questionnaire has been previously used in studies by Lio et al. (14) and Shahi et al. (15). The first part of the questionnaire was completed during patient admission by a trained researcher. The second part of the questionnaire was completed based on the anesthesia data

sheet after the patient recovered. The third part of the questionnaire was completed 20-36 hours after the surgery and after complete awakening of patients (15) through interview. The task of researcher was to simply record feeling and perceptions of the patients during surgery. Therefore, the patients' statements were not scored nor interpreted. The following yes or no questions were used in the questionnaire:

1. During the operation, did you notice any of the following: sounds, sight, being touched by others, pain, cold, heat and dreaming?
2. How was your mental state before the surgery? Calm, anxious, worried, scared, drowsy, hungry, in pain.
3. What was the last thing you remember before the anesthesia?
4. What is the first thing you remember after the surgery?
5. Can you remember anything between these two events?

Collected data were described as frequency and percentage. The data were analyzed in SPSS software (version 18) using the Chi-square test.

## RESULTS

Of 206 subjects enrolled in the study, 53.9% were men and 56.3% were undergoing abdominal surgery. In addition, 5.8% of the subjects were alcohol drinker (Table 1).

The patients in both groups did not experience hearing, sight, pain, cold, heat and touch during anesthesia and neither of them reported dreaming or any memory of the surgery and anesthesia. However, opium addicts were significantly more anxious at the night before surgery and felt more pain right after the surgery compared to non-addicted patients (Table 2).

**Table 2. Comparison of mental state of opium-addicted and non-addict patients at different times from the night before surgery to after surgery according to the patients' perception.**

| Group                    | Opium addicts |         |         |        |        |        |         | Non-addicts |         |         |        |        |        |         | P-value Chi-square |
|--------------------------|---------------|---------|---------|--------|--------|--------|---------|-------------|---------|---------|--------|--------|--------|---------|--------------------|

| The night before surgery | 11            | 46      | 9       | 16     | -      | -      | 22      | 16          | 38      | 17      | 8      | 4      | 2      | 17      | 0.03               |
| Surgery waiting room     | 9             | 45      | 28      | 15     | 3      | 3      | 1       | 18          | 43      | 22      | 13     | -      | 5      | 1       | 0.28               |
| Anesthesia induction     | 7             | 47      | 31      | 12     | 3      | 4      | -       | 14          | 42      | 28      | 13     | -      | -      | 5       | 0.01               |
| After the surgery        | 30            | 1       | 4       | 5      | 13     | 10     | 41      | 24          | 2       | 1       | 6      | 11     | 10     | 48      | 0.75               |

Pain and conversation with the nurse were the first things opium-addicted and non-addict patients remembered right after the surgery, respectively. Moreover, opium addicts reported fear of surgery and possible complications including disability as the main issues of concern between the night before surgery and anesthesia. In non-addicts, lack of general knowledge about the surgery and anesthesia, postoperative status and duration of hospital stay were the most frequent causes for concern during the mentioned period (Table 3).

**Table 3. Questions related to opium-addicted and non-addict patients' feelings between the night before surgery and after recovery**

|   | Variable  | Opium addicts | Non-addicts |
|---|---|---------------|-------------|
| <b>What is the last thing you remember before anesthesia?</b>                                   | Hunger  | 6%            | 4%          |
|   | Severe anxiety  | 12%           | 18%         |
|   | Thinking about death  | 10%           | 5%          |
|   | Thinking about family   | 15%           | 19%         |
|   | Pain  | 19%           | 17%         |
|   | Questions of anesthesiologist   | 24%           | 26%         |
|   | Sound of devices  | 14%           | 11%         |
| <b>What is the first thing you remember after anesthesia?</b>                                   | Pain  | 31%           | 27%         |
|   | Fear of death   | 11%           | 8%          |
|   | Ambient noise   | 28%           | 18%         |
|   | Other patients moaning  | 11%           | 9%          |
|   | The nurse's voice   | 19%           | 38%         |
| <b>What bothered you the most from the night before the surgery until after the anesthesia?</b> | Hunger  | 17%           | 21%         |
|   | Fear  | 34%           | 28%         |
|   | Pain  | 14%           | 11%         |
|   | Insomnia and fatigue  | 22%           | 9%          |
|   | Lack of general information about the surgery, postoperative status and length of hospital stay | 13%           | 31%         |

## DISCUSSION

In the present study, we investigated the occurrence of anesthesia awareness in patients undergoing pelvic and abdominal surgeries in two hospitals in Gorgan, northeastern Iran. Based on the results, none of the opium addicts and non-addicts experienced anesthesia awareness and recall. Inconsistent with our findings, Malek et al. reported opium addiction as a risk factor for anesthesia awareness in patients undergoing abdominal surgery (11). Another study also reported that consumption of opium or alcohol increases the required dose of anesthetics as well as the risk of anesthesia awareness (16). One of the most important goals during anesthesia is to create enough anesthetic depth, which is the key factor affecting anesthesia awareness and recall. Other studies have also reported that factors such as anxiety, pain threshold and drug sensitivity could affect depth of anesthesia (15). In addition, painful stimuli can affect memory suppression and reduce the depth of anesthesia. Therefore, patients' pain and anxiety level should be considered when determining the correct dose of anesthetics in order to create sufficient anesthetic depth (17). Baghaei Wadji and colleagues stated that higher cortisol levels in opium addicts may be a contributing factor to reduced anesthetic depth and increased risk of anesthesia awareness compared to non-addict patients (18).

Some studies have shown that preoperative injection of benzodiazepines such as midazolam in addition to sedation causes forgetfulness and reduces the recall of anesthesia events. In our study, midazolam was among the drugs that had been injected before surgery, which could be responsible in preventing anesthesia awareness and recall. Factors such as age, sex, weight, anesthesia class, type of surgery, etc. affect anesthesia awareness (15).

In a previous study, Forman claimed that patients always report a wide range of different experiences after general anesthesia including anesthesia awareness,

which can be preventable or unpreventable. The mentioned study also indicated that errors in the management and injection of anesthetics or technical errors such as serum pump failure, interruption of drug flow due to venous occlusion or leakage of anesthetic gas are often related to anesthesia awareness (16). Another study indicated that anesthesia awareness is generally more common among women and people aged over 65 years (19). Therefore, considering that anesthesia awareness can cause severe mental complications, such as post-traumatic stress syndrome, depression, anxiety attacks, sleep disorders, etc., all necessary technical precautions should be taken to prevent this issue in susceptible patients (16).

According to a previous study, anesthetic drugs are absorbed less effectively in patients who are anesthetized without opioids, which increases the likelihood of anesthesia awareness. The mentioned study also claimed that women, people with underlying diseases such as hypertension and patients aged 65 years or over are at higher risk of anesthesia awareness (19).

In general, anesthesia awareness is a multifactorial issue that may be influenced by several factors, including efficacy of anesthetics, surgical procedure, gender, mental state of the patients, use of neuromuscular-blocking drugs, duration of surgery, etc. Therefore, in modern clinical practice, special attention should be paid not only to physical issues and patients' rehabilitation, but also reduction of adverse effects on patients' mental health. Therefore, continuous monitoring during surgery is recommended to reduce the risk of awakening (19).

In this study we did not monitor or determine the patients' central body temperature, which could affect the sensitivity to anesthetic drugs. Therefore, it is recommended to consider this issue when conducting future studies. Mental health follow up during the first postoperative 24

hours and two weeks after the operation seems necessary to identify possible nightmares or any sign of anxiety (20). Although in the present study, none of the patients had anesthesia awareness, the presence of pain may lead to consciousness and recall during anesthesia (20), which should not be neglected.

## CONCLUSION

In the present study, none of the patients undergoing abdominal and pelvic surgery had anesthesia awareness. Moreover, opium addicts experience significantly higher level of anxiety the night before surgery compared to non-addicts. In addition, opium-addicted patients experience more pain immediately after recovery.
